Overview

An exploratory data analysis is carried out in order to develop a machine learning algorithm that could predict whether a breast cancer cell is benign or malignant until a final model. Results will be explained. Finally, the report will end with some concluding remarks.

Introduction

Breast cancer refers to a pathology in which a tumor develops in the breast tissue. Breast cancer is amongst the most common type of cancer in both sexes since 1975 and causes 411,000 annual deaths worldwide. Mammography is the most common mass screening tool for an early detection of breast cancers because of its sensitivity in recognising breast masses. After detection of suspicious breast masses, a biopsy test procedure would be carried out, such as Fine Needle Aspirates (FNA), that is the method this report focus on. This method has been showed to be safe, cost-effective, accurate and fast. A small drop of viscous fluid is aspired from the breast masses to be analysed under the microscope.

This project will make a performance comparison between different machine learning algorithms in order to to assess the correctness in classifying data with respect to efficiency and effectiveness of each algorithm in terms of accuracy, precision, sensitivity and specificity, in order to find the best diagnosis. The utilization of data science and machine learning approaches in medical fields proves to be prolific as such approaches may be considered of great assistance in the decision making process of medical practitioners.

Github - https://github.com/dj-sarkar/breastcancer

Aim of the project

The objective of this report is to train machine learning models to predict whether a breast cancer cell is Benign or Malignant. Data will be transformed and its dimension reduced to reveal patterns in the dataset and create a more robust analysis. The optimal model will be selected following the resulting accuracy, sensitivity, and f1 score, amongst other factors. The metrics will be defined later in the process. Machine learning method can be used to extract the features of cancer cell nuclei image and classify them. It would be helpful to determine whether a given sample appears to be Benign ("B") or Malignant ("M").

The machine learning models in this report will try to create a classifier that provides a high accuracy level combined with a low rate of false-negatives (high sensitivity).

Dataset

The present report covers the Breast Cancer Wisconsin (Diagnostic) DataSet (https://www.kaggle.com/uciml/breast-cancer-wisconsin-data/version/2) created by Dr. William H. Wolberg, physician at the University Of Wisconsin Hospital at Madison, Wisconsin, USA. The data used for this project was collected in 1993 by the University of Wisconsin and it is composed by the biopsy result of 569 patients in Wisconsin Hospital.

```

The dataset's features describe characteristics of the cell nuclei on the image. The features information are specified below:

- Attribute Information:
 - 1. ID number
 - 2. Diagnosis (M = malignant, B = benign)
- Ten features were computed for each cell nucleus:
- 1. radius: mean of distances from center to points on the perimeter
- 2. texture: standard deviation of grey-scale values
- 3. perimeter
- 4. area: Number of pixels inside contour $+ \frac{1}{2}$ for pixels on perimeter
- 5. smoothness: local variation in radius lengths), , t
- 6. compactness: perimeter 2 / area 1.0; this dimensionless number is at a minimum with a circular disk and increases with the irregularity of the boundary, but this measure also increases for elongated cell nuclei, which is not indicative of malignancy
- 7. concavity: severity of concave portions of the contour
- 8. concave points: number of concave portions of the contour
- 9. symmetry
- 10. fractal dimension: "coastline approximation" 1; a higher value corresponds a less regular contour and thus to a higher probability of malignancy

The mean, standard error and "worst" or largest (mean of the three largest values) of these features were computed for each image, resulting in 30 variables. From this diagnosis, 357 of the cases were classified as benign tumors and 212 were considered malignant tumors. All cancers and some of the benign masses were histologically confirmed

The column 33 is invalid.

```
data$diagnosis <- as.factor(data$diagnosis)
# The 33rd column is invalid
data[,33] <- NULL</pre>
```

Methods and Analysis

Data Analysis

By observing our dataset, it was found that it contains 569 observations with 32 variables.

```
str(data)
```

```

There aren't NA values. By analysing the dataset, it is found that it is a bit unbalanced in its proportions:

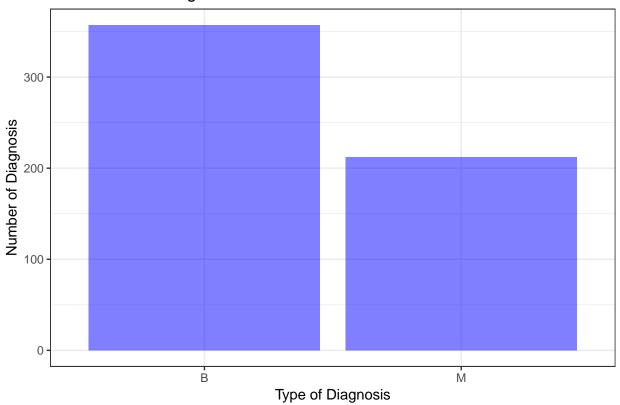

```
# Check data proportions
prop.table(table(data$diagnosis))

##
## B M
## 0.6274165 0.3725835
```

Also the plot of proportions confirms that the target variable is slightly unbalanced.

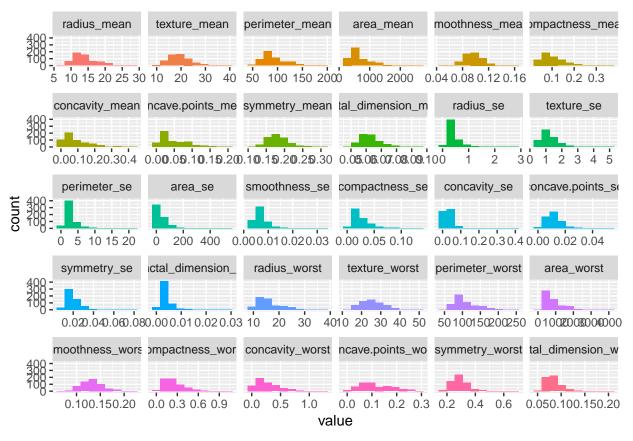

```
# Histogram of Distribution of Diagnosis
options(repr.plot.width=4, repr.plot.height=4)
ggplot(data, aes(x=diagnosis)) +
  geom_bar(fill="blue",alpha=0.5) +
  xlab("Type of Diagnosis") + ylab("Number of Diagnosis") +
  theme_bw()+labs(title="Distribution of Diagnosis")
```

Distribution of Diagnosis

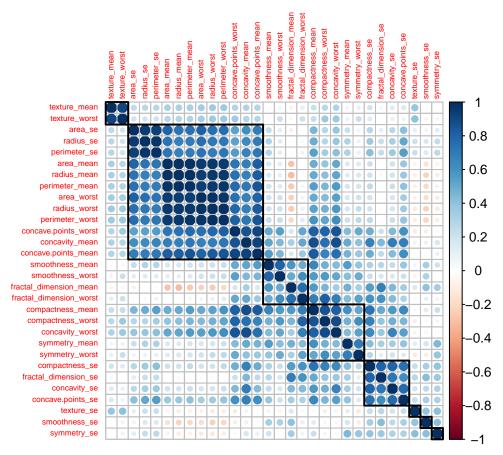

The most variables of the dataset are normally distributed as show with the below plot:

```
# Plot of the variable distribution
plot_num(data %>% select(-id), bins=10)
```

Check if the is any correlation between variables as machine learning algorithms assume that the predictor variables are independent from each others.

```
# Correlation Matrix
correlationMatrix <- cor(data[,3:ncol(data)])
corrplot(correlationMatrix, order = "hclust", tl.cex = 0.5, addrect = 8)</pre>
```

As shown by this plot, many variables are highly correlated with each others. Many methods perform better if highly correlated attributes are removed. The Caret R package provides the findCorrelation which will analyze a correlation matrix of your data's attributes report on attributes that can be removed. Because of much correlation some machine learning models could fail.

```
# Attributes that are highly corrected (ideally >0.90)
highlyCorrelated <- findCorrelation(correlationMatrix, cutoff=0.9)
# Indices of highly correlated attributes
print(highlyCorrelated)</pre>
```

[1] 7 8 23 21 3 24 1 13 14 2

Selecting the right features in data can mean the difference between mediocre performance with long training times and great performance with short training times.

```
# Remove correlated variables
data2 <- data %>%select(-highlyCorrelated)
# Check column count after removing correlated variables
ncol(data2)
```

[1] 22

The new dataset has loss 10 variables.

Modeling Approach

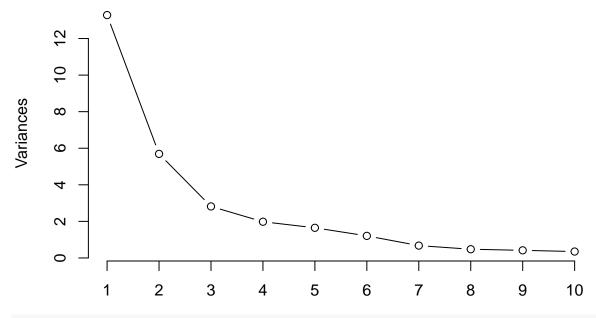

Modeling

Principal Component Analysis (PCA).

To avoid redundancy and relevancy, the function 'prncomp' was used to calculate the Principal Component Analysis (PCA) and select the rights components to avoid correlated variables that can be detrimental to our clustering analysis. One of the common problems in analysis of complex data comes from a large number of variables, which requires a large amount of memory and computation power. This is where PCA comes in. It is a technique to reduce the dimension of the feature space by feature extraction. The main idea of PCA is to reduce the dimensionality of a data set consisting of many variables correlated with each other, either heavily or lightly, while retaining the variation present in the dataset, up to the maximum extent. The same is done by transforming the variables to a new set of variables, which are known as the principal components (or simply, the PCs) and are orthogonal, ordered such that the retention of variation present in the original variables decrease as one moves down in the order.

```
# Plot of PCA
pca_res_data1 <- prcomp(data[,3:ncol(data)], center = TRUE, scale = TRUE)
plot(pca_res_data1, type="l", main = "PCA")</pre>
```

PCA

## Standard deviation
                          0.07375
## Proportion of Variance 0.00027
## Cumulative Proportion 1.00000
```

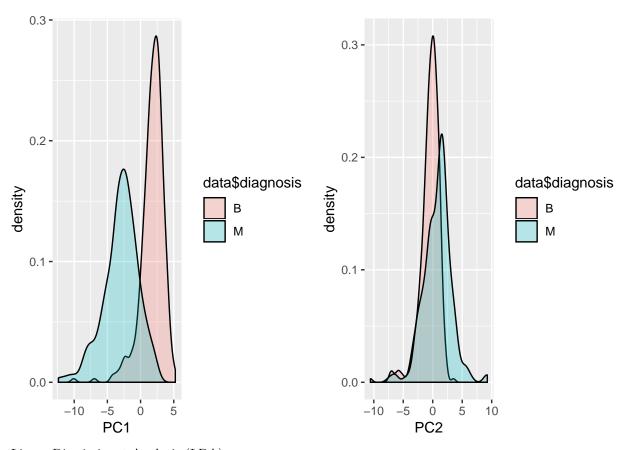

The above table shows that 95% of the variance is explained with 8 PC's in the transformed dataset data2.

The data of the first 2 components can be easly separated into two classes. This is caused by the fact that the variance explained by these components is not large. The data can be easly separated.

```
# Compare plot of Diagnosis
g_pc1 <- ggplot(pca_df, aes(x=PC1, fill=data$diagnosis)) +
   geom_density(alpha=0.25)
g_pc2 <- ggplot(pca_df, aes(x=PC2, fill=data$diagnosis)) +</pre>
```

Linear Discriminant Analysis (LDA)

Another approach is to use the Linear Discriminant Analysis (LDA) instead of PCA. LDA takes in consideration the different classes and could get better results. The particularity of LDA is that it models the distribution of predictors separately in each of the response classes, and then it uses Bayes' theorem to estimate the probability. It is important to know that LDA assumes a normal distribution for each class, a class-specific mean, and a common variance.

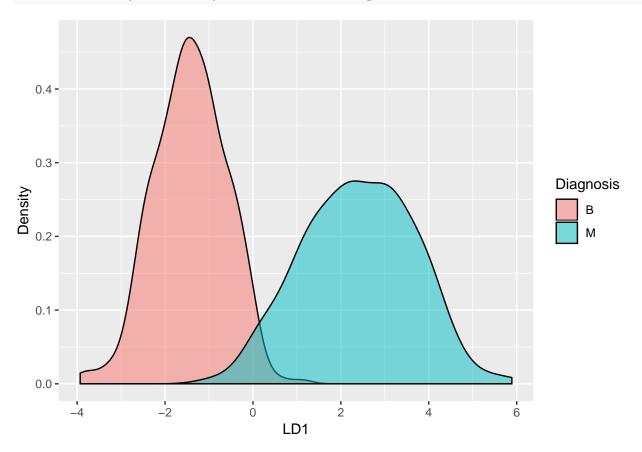

```
lda_res_data <- MASS::lda(diagnosis~., data = data, center = TRUE, scale = TRUE)
lda_res_data</pre>
```

```

Model Creation

It is necessary to have a training and a testing set when building some models. One can split the modified dataset into Train (80%) and Test (20%), in order to predict is whether a cancer cell is Benign or Malignant, by building machine learning classification models.

Naive Bayes Model

The Naive Bayesian classifier is based on Bayes' theorem with the independence assumptions between predictors. A Naive Bayesian model is easy to build, with no complicated iterative parameter estimation which makes it particularly useful for very large datasets. Bayes theorem provides a way of calculating the posterior probability, P(c|x), from P(c), P(x), and P(x|c). Naive Bayes classifier assume that the effect of the value of a predictor (x) on a given class (c) is independent of the values of other predictors. This assumption is called class conditional independence.

##
```

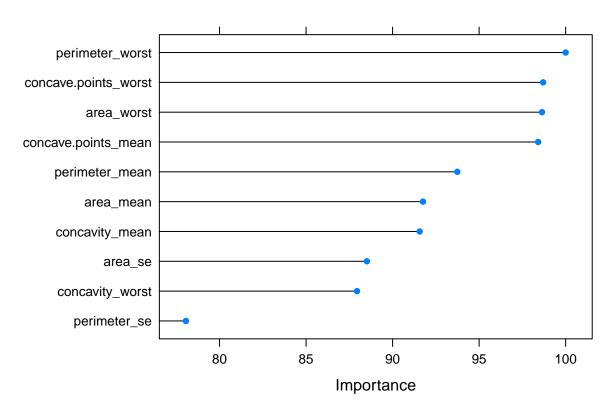

One can note the accuracy with such model. These metrics will be described later, where: Sensitivity (recall) represent the true positive rate: the proportions of actual positives correctly identified. Specificity is the true

negative rate: the proportion of actual negatives correctly identified. Accuracy is the general score of the classifier model performance as it is the ratio of how many samples are correctly classified to all samples. F1 score: the harmonic mean of precision and sensitivity. Accuracy and F1 score would be used to compare the result with the benchmark model. Precision: the number of correct positive results divided by the number of all positive results returned by the classifier.

The most important variables that permit the best prediction and contribute the most to the model are the following:

```
# Plot of Naive Bayes

Logistic Regression Model

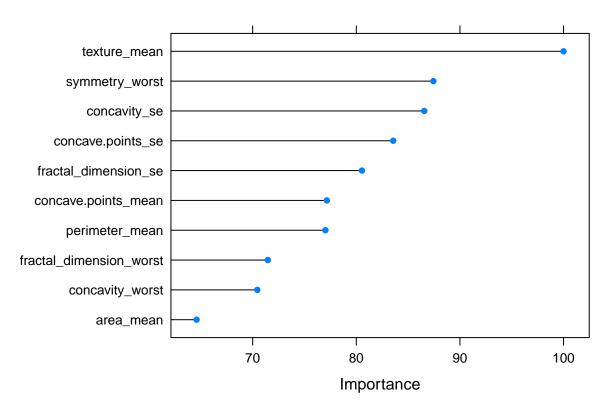

Logistic Regression is widly used for binary classification like (0,1). The binary logistic model is used to estimate the probability of a binary response based on one or more predictor (or independent) variables (features).

Random Forest Model

Random forests are a very popular machine learning approach that addresses the shortcomings of decision trees using a clever idea. The goal is to improve prediction performance and reduce instability by averaging multiple decision trees (a forest of trees constructed with randomness). Random forest is another ensemble method based on decision trees. It split data into sub-samples, trains decision tree classifiers on each sub-sample and averages prediction of each classifier. Splitting dataset causes higher bias but it is compensated by large decrease in variance. Random Forest is a supervised learning algorithm and it is flexible, easy to use machine learning algorithm that produces, even without hyper-parameter tuning, a great result most of the time. It is also one of the most used algorithms, because of it's simplicity and the fact that it can be used for both classification and regression tasks. Random forest builds multiple decision trees and merges them together to get a more accurate and stable prediction.

K Nearest Neighbor (KNN) Model

KNN (K-Nearest Neighbors) is one of many (supervised learning) algorithms used in data mining and machine learning, it's a classifier algorithm where the learning is based "how similar" is a data from other. K nearest neighbors is a simple algorithm that stores all available cases and classifies new cases based on a similarity measure (e.g., distance functions).

```
# Confusion Matrix
model_knn <- train(diagnosis~.,</pre>

Neural Network with PCA Model

Artificial Neural Networks (NN) are a types of mathematical algorithms originating the simulation of networks of biological neurons. An artificial Neural Network consists of nodes (called neurons) and edges (called synapses). Input data is transmitted through the weighted synapses to the neuronswhere calculations are processed and then either sent to further neurons or represent the output.

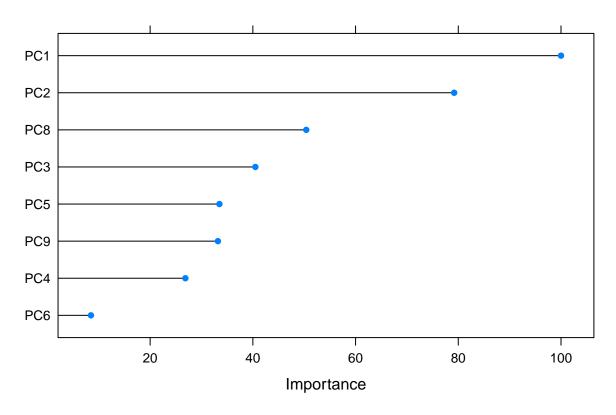

Neural Networks take in the weights of connections between neurons . The weights are balanced, learning data point in the wake of learning data point . When all weights are trained, the neural network can be utilized to predict the class or a quantity, if there should arise an occurrence of regression of a new input data point. With Neural networks, extremely complex models can be trained and they can be utilized as a kind of black box, without playing out an unpredictable complex feature engineering before training the model. Joined with the "deep approach" even more unpredictable models can be picked up to realize new possibilities.

                 0.7272727 0.9090909 1.0000000 0.9520202
                                                                       1
                                                                            0
```

From the following plot, one can observe two models, Naive_bayes and Logistic_regr have great variability, depending of the processed sample :

The Neural Network LDA model achieve a great auc (Area Under the ROC Curve) with some variability. The ROC (Receiver Operating characteristic Curve is a graph showing the performance of a classification

model at all classification thresholds) metric measure the auc of the roc curve of each model. This metric is independent of any threshold. Let's remember how these models result with the testing dataset. Prediction classes are obtained by default with a threshold of 0.5 which could not be the best with an unbalanced dataset like this.

```
# Gather Confusion Matrix results
confusionmatrix_list <- list(
   Naive_Bayes=confusionmatrix_naiveb,
   Logistic_regr=confusionmatrix_logreg,
   Random_Forest=confusionmatrix_randomforest,
   KNN=confusionmatrix_knn,
   Neural_PCA=confusionmatrix_nnet_pca,
   Neural_LDA=confusionmatrix_nnet_lda)
confusionmatrix_list_results <- sapply(confusionmatrix_list, function(x) x$byClass)
confusionmatrix_list_results %>% knitr::kable()

Discussion

Below the metrics that will compare in this section have been described.

Accuracy is our starting point. It is the number of correct predictions made divided by the total number of predictions made, multiplied by 100 to turn it into a percentage.

Precision is the number of True Positives divided by the number of True Positives and False Positives. Put another way, it is the number of positive predictions divided by the total number of positive class values predicted. It is also called the Positive Predictive Value (PPV). A low precision can also indicate a large number of False Positives.

Recall (Sensitivity) is the number of True Positives divided by the number of True Positives and the number of False Negatives. Put another way it is the number of positive predictions divided by the number of positive class values in the test data. It is also called Sensitivity or the True Positive Rate. Recall can be thought of as a measure of a classifiers completeness. A low recall indicates many False Negatives.

The F1 Score is the 2 x ((precision x recall) / (precision + recall)). It is also called the F Score or the F Measure. Put another way, the F1 score conveys the balance between the precision and the recall.

The best results for sensitivity (detection of breast cancer malign cases) is Neural Netword with LDA model which also has a great F1 score.

Conclusion

This paper treats the Wisconsin Madison Breast Cancer diagnosis problem as a pattern classification problem. In this report several machine learning model were investigated and the optimal model was selected by choosing a high accuracy level combinated with a low rate of false-negatives (the means that the metric is high sensitivity).

The Neural Netword with LDA model has the optimal results for F1 (0.9879518), Sensitivity (0.9761905) and Balanced Accuracy (0.9880952)
